# An Inexact Bundle Approach to Cutting-Stock Problems 

Krzysztof C. Kiwiel<br>Systems Research Institute, Newelska 6, 01-447 Warsaw, Poland, kiwiel@ibspan.waw.pl

We show that the LP relaxation of the cutting-stock problem can be solved efficiently by the recently proposed inexact bundle method. This method saves work by allowing inaccurate solutions to knapsack subproblems. With suitable rounding heuristics, our method solves almost all the cutting-stock instances from the literature.

Fiey words: nondifferentiable convex optimization, Lagrangian relaxation, integer progranming, bunclle metlools, knapsack problems, cutting-stock
History: Initial version April 2005; revised May 2006; October 2006; September 2008.

## 1. Introduction

The classic Gilmore and Gomory (1961) formulation of the cutting-stock problem (CSP) is usually solved by LP-based column generation, rounding heuristics and branch-and-bound; see, e.g., (Belov and Scheithauer, 2002, 2006; Degraeve and Peeters, 2003; Degraeve and Sclnage, 1999; Vance, 1998; Vanderbeck, 1999). Since column generation (CG) applied to its LP relaxation may converge slowly, there is interest in stabilized variants based on LP or QP (Ben Amor et al., 2004; Ben Amor and Valério de Carvalho, 2005; Briant et al., 2007). Alteruatively, the highly efficient hybrid approach of Degraeve and Peeters (2003) generates additional columns by applying subgradient optimization to its Lagrangian relaxation.

In this paper we show that its LP relaxation can also be solved efficiently by the inexact bundle method of Kiwiel (2006a). This QP-based method saves work by allowing inaccurate solutions to Lagrangian subproblems. For the CSP, each subproblem is a knapsack problem (KP). We give a simple test for inexact $K P$ solutions (see $\S 2.2$ below) that works well in practice for a standard branch-and-bound KP solver of Martello and Toth (1990). Further, to avoid the difficulties arising when a bounded KP is transformed into a 0-1 KP (Vanderbeck, 2002), we use relaxed bounds. Next, by adapting the ideas of (Belov and Scheithauer, 2002; Holthaus, 2002; Stadtler, 1990; Wäscher and Gau, 1996) to our inexact framework, we give rounding heuristics that solve almost all the CSP instances from the literature; in particular, they perform better than the best heuristics of Wäscher and Gau (1996). In effect, our
inexact KP solutions, bound relaxation and rounding heuristics should be of interest also for other, more traditional CG-based approaches to the CSP.

We now provide a historical perspective for our contributions. Our work was inspired by Briant et al. (2007), where (together with four other applications) the LP relaxation of the CSP was solved by several variants of CG and a standard bundle method. On some CSP instances, bundle was much slower than CG, mostly because its subproblems were more difficult for the IKP solver of Vanderbeck (2002). Hence Claude Lemarechal suggested the CSP as a testing example for our inexact bundle (Kiwiel, 2006a). For technical reasons, instead of the KP solver of Vanderbeck (2002), we used the MT1R procedure of Martello and Toth (1990). Our initial quite disappointing results improved greatly once we used relaxed KP bounds and inexact solutions: our method became much faster in practice than all the algorithms tested in (Briant et al., 2007, §2.2) (see §5.8). Next, we collected more test instances and adapted some rounding heuristics from the literature. The main aim was to appraise our inexact bundle solutions: they are deemed accurate enough if the heuristics solve almost all instances.

We now summarize our findings on admissible inexactness. The relative accuracy in dual function evaluations is controlled by the tolerance $\epsilon_{r}$ of our KP solver (cf. §2.2). First, for $\epsilon_{r}=0$ (i.e., exact bundle), the average computing times are much greater than those for $\epsilon_{r}=10^{-5}$ (usually by factors of 30 or more), although the iteration numbers and the heuristic performance are almost the same. Second, the iteration numbers and timings are close for $\epsilon_{r}=10^{-3}, 10^{-4}$ and $10^{-5}$; however, relative to $\epsilon_{r}=10^{-5}$, our heuristics perform much worse for $\epsilon_{r}=10^{-3}$, and just marginally worse for $\epsilon_{r}=10^{-4}$. Third, further experiments (not reported here for brevity) gave very close results for $\epsilon_{\tau}=10^{-5}, 10^{-6}, 10^{-7}$ and $10^{-8}$. To sum up, $\epsilon_{r}=10^{-5}$ seems to be a good borderline choice. On the other hand, since in the CSP the gap between the primal value and the relaxed dual value is usually less than 1 , and either rounding heuristics or branch-and-bound should "close" this gap, it may seem more appropriate to ensure a given absolute accuracy $\epsilon_{a}<1$ in dual function evaluations (see §5.6.3). Quite suprisingly, our results for a fairly large $\epsilon_{a}=0.01$ are very close to those for $\epsilon_{r}=10^{-5}$, whereas for $\epsilon_{a}=0.05$ our heuristics perform slightly worse.

We thus present the first successful application of our inexact bundle method. Our approach is also useful for the conic bundle variant of Kiwiel and Lemaréchal (2007).

The paper is organized as follows. In $\S 2$ we recall the classic CSP model of Gilmore and Gomory (1961) and introduce inexact KP solutions for its Lagrangian relaxation. Our
rounding heuristics are given in $\S 3$ in a general form suitable for other CSP solvers. The inexact bundle method is reviewed in $\S 4$. Our computational results are presented in $\S 5$.

## 2. Lagrangian relaxation of the CSP

The one-dimensional cutting-stock problem (CSP) is to minimize the number of stock pieces of width $W$ used to meet the demands $d_{i}$ for items to be cut at their widths $w_{i} \in(0, W)$, for $i=1, \ldots, m$. The bin-packing problem (BPP) is a special case of the CSP with unit clemands.

### 2.1. The Gilmore-Gomory model

This classic model is formulated as follows. Denote the set of cutting patterns by

$$
\begin{equation*}
P:=\left\{p \in \mathbb{Z}_{+}^{m}: w p \leq W\right\} \tag{1}
\end{equation*}
$$

Let $z_{\mu}$ be the number of times pattern $p$ is used. The original model has the form

$$
\begin{equation*}
\min \sum_{p \in P} z_{p} \text { s.t. } \quad \sum_{p \in P} p z_{p} \geq d, z \in \mathbb{Z}_{+}^{|P|} . \tag{2a}
\end{equation*}
$$

For Lagrangiau relaxation we augment this model with the redundant constraint

$$
\begin{equation*}
\sum_{p \in P} z_{p} \leq N \tag{2b}
\end{equation*}
$$

where $N$ is an upper bound on the optimal value of (2a) (e.g., $N=\sum_{i} d_{i}$ ); this ensures boundedness of the ground set $Z:=\left\{z \in \mathbb{Z}_{+}^{|P|}: \sum_{p} z_{p} \leq N\right\}$. Relaxing the demand constraint $\sum_{p} p z_{p} \geq d$ witll a price vector $u$ yields the Lagrangian $L(z ; u):=\sum_{p} z_{p}+u\left(d-\sum_{p} p z_{p}\right)$ and the dual function

$$
\begin{equation*}
\theta(u):=\min _{z \in Z}\left\{L(z ; u)=u d+\sum_{p \in P}(1-u p) z_{p}\right\} . \tag{3}
\end{equation*}
$$

The Lagrangian subproblem above may be solved by finding a solution $p(u)$ of the KP

$$
\begin{equation*}
p(u) \in \operatorname{Arg} \max \{u p: p \in P\}=\operatorname{Arg} \max \left\{u p: w p \leq W, p \in \mathbb{Z}_{+}^{m}\right\} \tag{4}
\end{equation*}
$$

and taking $z_{p(u)}=N$ and $z_{p}=0$ for $p \neq p(u)$ if $u p(u)>1, z=0$ otherwise, thus producing

$$
\begin{equation*}
\theta(u)=u d+N[1-u p(u)]_{-}, \tag{5}
\end{equation*}
$$

where $[\cdot]_{-}:=\min \{\cdot, 0\}$. Let $v_{*}$ and $v_{L P}$ denote the optimal values of (2) and its LP relaxation, respectively. It is well known that $v_{L P}$ coincides with the dual optimal value

$$
\begin{equation*}
\theta_{*}:=\max \left\{\theta(u): u \in \mathbb{R}_{+}^{m}\right\} \tag{6}
\end{equation*}
$$

Experiments show that $\breve{u}:=w / W$ is a good initial estimate of solutions to the Lagrangian dual (6) (Ben Amor and Valério de Carvalho, 2005, §4), (Briant et al., 2007, §2). In fact $\check{u}$ minimizes the relaxed dual function

$$
\begin{equation*}
\theta_{L P}(u):=u d+N[1-u \underline{p}(u)]_{-}, \tag{7}
\end{equation*}
$$

where $\underline{p}(u)$ solves the LP relaxation of (4). (Since $\theta_{L P}(\check{u})=\check{u} d \leq v_{*} \leq N$, we see that $-d=-N(\check{u} d / N)(d / \tilde{u} d)$ is a subgradient of the second term of (7) at $\left.\check{u}: 0 \in \partial \theta_{l . P}(\tilde{u}).\right)$

### 2.2. Inexact KP solutions

To strengthen our relaxation, we may consider only proper patterns $p$ such that,

$$
\begin{equation*}
p \leq b \quad \text { with } \quad b_{i}:=\operatorname{ain}\left\{d_{i},\left\lfloor W / w_{i}\right\rfloor\right\}, \quad i=1: m \tag{8}
\end{equation*}
$$

Indeed, adding the bound $p \leq b$ to (1) and (4) does not change $v_{*}$, but it may raise $v_{L P}$ (Nitsche et al., 1999). Then the CG subproblem (4) becomes a bounded KP, which can be tumed into a 0-1 KP via the transformation of (Martello and Toth, 1990, §3.2). However, this transformation may duplicate solution representations, thus creating difficulties for $0-1$ KP solvers (Vanderbeck, 2002). To avoid duplicates, we may use the relaxed bound

$$
\begin{equation*}
p \leq b^{\prime} \quad \text { with } \quad b_{i}^{\prime}:=2^{\left[\log _{2}\left(b_{i}+1\right)\right\rceil}-1, \quad i=1: m, \tag{9}
\end{equation*}
$$

which comesponds to replacing $d_{2}$ in (8) by the smallest number of the form $2^{j}-1$ with $j \geq 1$ such that $2^{j}-1 \geq d_{i}\left(2 d_{i}-1\right.$ in the worst case); the number of transformed variables is the same. We solve the transformed KP by a double precision version of the branch-and-bound procedure MT1R of Martello and Toth (1990). To reduce its work, we allow MT1R to find an approximate solution for a given relative accuracy tolerance $\epsilon_{r}$. Namely, the backtracking step exits if $\zeta \geq\left(1-\epsilon_{r}\right) \bar{\zeta}$, where $\zeta:=u p$ for the incumbent $p$ and $\bar{\zeta}$ is MT1R's upper bound on the optimal value $u p(u)$. Hence, by (5), we have the accuracy estimates

$$
\begin{gather*}
\underline{\theta}(u):=u d+N(1-\bar{\zeta})_{-} \leq \theta(u) \leq \bar{\theta}(u):=u d+N(1-\zeta)_{-},  \tag{10a}\\
\bar{\theta}(u)-\underline{\theta}(u) \leq N(\bar{\zeta}-\zeta) \leq N \epsilon_{r} \bar{\zeta} . \tag{10b}
\end{gather*}
$$

For a normal exit with an optimal $p=p(u)$, we may replace $\bar{\zeta}$ by $\zeta$ and $\epsilon$. by 0 in (10).
As for our choice of MT1R, we add that Valério de Carvalho (2005) used MTTR as well, Belov and Scheithauer (2006) employed a similar branch-and-bound solver, whereas Vanderbeck (1999) and Briant et al. (2007) used the more specialized branch-and-bound solver of Vanderbeck (2002). On the other hand, Degraeve and Peeters (2003) employed a similar branch-and-bound solver but with prices multiplied by 10,000 and rounded to integers, without discussing the effects of inexact KP solutions. Further, more recent KP solvers (Kellerer et al., 2004) accept integer data only; hence their use with suitable price roundings is left open for a future study. To sum up, MT1R is outdated, but we could not fincl anything better, and we believe that the current, results will serve as a useful yardstick for future work with modern KP solvers.

## 3. Heuristic rounding of relaxed solutions

Typical rounding heuristics for the CSP proceed as follows; cf. (Belov and Scheithauer, 2002, 2000; Degraeve and Peeters, 2003; Holthaus, 2002; Scheithaner et al., 2001; Stadtler, 1990; Wäsclier and Gau, 1996). A solution $\tilde{z}$ of the LP relaxation is rounded down into an integer solution $\bar{z}:=\lfloor\hat{z}\rfloor$. Next, a sequential heuristic applied to the residual problem (2) with $d$ replaced by $d^{\prime}:=d-\sum_{p} p \bar{z}_{p}$ delivers a residual solution $\tilde{z}$. Then the sum $\bar{z}+\bar{z}$ serves as a possibly inexact solution of (2) (which is exact if its value is equal to a lower bound on $u_{*} ;$ e.g., $\left\lceil u_{L p}\right\rceil$ ). Since for simple rounding down $(\bar{z}=\lfloor\bar{z}\rfloor)$, the residual problem may be too large to be solved optimally by a heuristic, some components of $\bar{z}$ may be increased (Holthaus, 2002; Scheithauer et al., 2001); however, if the residual problem becomes too surall to produce a solution to the original problem, some components of $\bar{z}$ may be decreased (Belov and Scheithauer, 2002).

In $\S 3.1$ we give a general rounding procedure, which angments the ideas of Belov and Scheithauer (2002) and Holthaus (2002) with the oversupply reduction of Stadtler (1990). As for sequential heuristics, in $\S 3.2$ we describe minor (but useful) modifications of the first-fit-clecreasing (FFD) of Chvátal (1983) and the heuristics of Belov and Scheithaner (2007) and Holthaus (2002). Since it pays to call lighter heuristics first, useful combinations of rounding and sequential heuristics are detailed in §3.3.

We add that the rounding procedures of (Vanderbeck, 1999, §3.7) and (Wäscher and Gau, 1996, RSUC) would be difficult to implement in our context. As for sequential heuristics, we
also tried the best-fit-decreasing of Chvátal (1983) and the fill bin heuristics of Vanderbeck (1999), but they did not perform significantly better than FFD in our trials.

### 3.1. A general rounding procedure

Numbering the patterns so that $P=\left\{p^{j}\right\}_{j=1}^{n}$, we may write (2a) as

$$
\begin{equation*}
\min \sum_{j=1}^{n} z_{j} \quad \text { s.t. } \quad \sum_{j=1}^{n} p^{j} z_{j} \geq d, z \in \mathbb{Z}_{+}^{n} . \tag{11}
\end{equation*}
$$

Given an incumbent solution $z^{*}$ of (11) (e.g., found by FFD) and a point $\hat{z} \in \mathbb{R}_{+}^{n}$ (e.g., found by LP relaxation), the following procedure attempts to improve $z^{*}$ by calling a heuristic on residual problems derived from rounded variants of $\hat{z}$. Let $e:=(1, \ldots, 1) \in \mathbb{R}^{n}$.

Procedure 1 (Rounding procedure).
Step 1 (Rounding down). Set $\bar{z}:=\lfloor\hat{z}\rfloor$ and $d^{\prime}:=d-\sum_{j} p^{j} \bar{z}_{3}$. Sort the fractional parts $r_{j}:=\hat{z}_{j}-\bar{z}_{j}$ so that $r_{j_{1}} \geq \ldots \geq r_{j_{n}}$, and set $\bar{n}:=\left|\left\{j: r_{j}>0\right\}\right|$.

Step 2 (Oversupply reduction). While $d^{\prime} \not \geq 0$, pick $\bar{\jmath}$ to maximize

$$
\begin{equation*}
\sum_{i: d_{i}^{\prime}<0} w_{i} \min \left\{p_{i}^{j},-d_{i}^{\prime}\right\} \tag{12}
\end{equation*}
$$

over $j$ s.t. $\bar{z}_{j}>0$, set $\bar{z}_{\bar{j}}:=\bar{z}_{j}-1$ and $d^{\prime \prime}:=d^{\prime}+p^{\bar{\jmath}}$.
Step 3 (Partial rounding up). Set $I:=0$. For $i=1: \bar{n}_{1}$ if $p^{j_{i}} \leq d^{\prime}$, set $\bar{z}_{j_{i}}=\bar{z}_{j_{2}}+1$, $d^{\prime}:=d^{\prime}-p^{j_{i}}, I:=I \cup\left\{j_{i}\right\}$.

Step 4 (Heuristic improvement). Using a heuristic, find a feasible point $\tilde{z}$ for the residual problem (11) with $d$ replaced by $d^{\prime}$. If $e \bar{z}+e \tilde{z}<e z^{*}$, set $z^{*}:=\bar{z}+\tilde{z}$.

Step 5 (Residual problem extension). If $I \neq \emptyset$, remove from $\bar{I}$ its last entry $j$, set $\bar{z}_{j}:=\bar{z}_{j}-1$, $d^{\prime \prime}:=d^{\prime}+p^{\prime}$ and return to Step 4.

If $\tilde{z}$ solves the LP relaxation of an equality-constramed CSP, our procedure reduces to the one in (Belov and Scheithauer, 2002, §2.5); otherwise Step 2 (due to (Stadtler, 1990, Fig. 3)) helps. Following (Belov and Scheithaner, 2002, §5.2), our implementation allows at most ten returns from Step 5.

One of our heuristics uses the following modification of Step 3 , based on the ideas in (Holthaus, 2002, §3.2).

Step 3' (Partial rounding up). Set $I:=\emptyset, K:=\left\{j: p^{j} \leq d^{\prime}, r_{j}>0\right\}$. While $K^{\prime} \neq 0$, pick $\bar{\jmath}$ to maximize $\sum_{i} p_{i}^{j}$ over $j \in K$, set $\bar{z}_{\bar{j}}=\bar{z}_{j}+1, d^{\prime}:=d^{\prime}-p^{\bar{j}}, I:=I \cup\{\bar{j}\}, K:=\{j \in K:$ $\left.p^{j} \leq d^{\prime}, j \neq \bar{\jmath}\right\}$.

### 3.2. Sequential heuristics

We now describe our heuristics for the residual problem (2a) with $d$ replaced by $d^{\prime} \geq 0$. We assume that $w_{1} \geq \ldots \geq w_{m}$.

Our implementation of FFD works as follows. Set $\tilde{z}:=0, d^{\prime \prime}:=d^{\prime}$. While $d^{\prime \prime} \neq 0$, generate the next pattern $p$ by setting

$$
\begin{equation*}
p_{i}:=\min \left\{d_{i}^{\prime \prime},\left\lfloor\left(W-\sum_{j<i} w_{j} p_{j}\right) / w_{i}\right\rfloor\right\} \quad \text { for } i=1: m \tag{13}
\end{equation*}
$$

set $\kappa:=\min \left\{\left\lfloor d_{i}^{\prime \prime} / p_{i}\right\rfloor: p_{i}>0\right\}, \tilde{z}_{p}:=\bar{z}_{p}+\kappa, d^{\prime \prime}:=d^{\prime \prime}-\kappa p$. The version of (Clivátal, 1983, p. 208) employs $\kappa \equiv 1$, and hence is less efficient for large demands.

Our modification of the sequential heuristic procedure (SHP) of (Holthaus, 2002, §3.2), given a price vector $\hat{u} \in \mathbb{R}^{m}$ (e.g., an approximate solution of (6)) and a price tolenunce $u_{\text {tol }}>0$ for romanding errors (we use $u_{\text {tol }}=10^{-12}$ ), sets $\bar{u}_{i}:=\max \left\{\bar{u}_{i}, u_{\text {tol }}\right\}$ for $i=1: m$ and replaces the FFD formula (13) by the bounded KP

$$
\begin{equation*}
p \in \operatorname{Arg} \max \left\{\bar{u} p: w p \leq W, p \leq d^{\prime \prime}, p \in \mathbb{Z}_{+}^{m}\right\} \tag{14}
\end{equation*}
$$

Our implementation of the sequential value correction (SVC) heuristic of (Belov and Scheithauer, 2007, $\S 2$ ) records the best solution found by calling SHP at most thirty times with $\bar{u}$ modified as follows. Initially $\bar{u}_{i}:=\max \left\{1, W \hat{u}_{i}\right\}, i=1: m$. If $w d^{\prime \prime} \notin W$, then after solving (14) and updating $d^{\prime \prime}$, for $i$ such that $p_{i}>0$, set

$$
\begin{equation*}
\bar{u}_{i}:=\left[\gamma_{i} \bar{u}_{i}+(W / w p) w_{i}^{1.04}\right] /\left(\gamma_{i}+1\right) \quad \text { with } \quad \gamma_{i}:=\Omega_{i}\left(d_{i}^{\prime}+d_{i}^{\prime \prime}\right) / p_{i} \tag{15}
\end{equation*}
$$

for $\Omega_{i}$ picked randomly in $\left[1 / \Omega_{i}^{\prime}, \Omega_{i}^{\prime}\right]$, where $\Omega_{i}^{\prime}$ is chosen at random in [1, 1.5]. An early exit occurs if SHP finds $\tilde{z}$ such that $e \bar{z}+e \tilde{z}=\lceil\theta(\hat{u})\rceil$, in which case $z^{*}:=\bar{z}+\tilde{z}$ is optimal.

### 3.3. Combinations of rounding and sequential heuristics

We now give more details on the five heuristics used in our experiments. The heuristics are described as if being called by a general solver for the LP relaxation of (11), which could be any variant of the CG procedure or the bundle method given in $\S 4$.

Our initial heuristic H0 calls FFD with $d^{\prime}=d$ (i.e., on the original problem) to initialize the incumbent $z^{*}:=\tilde{z}$, the upper bound $N:=e z^{*}$ and the lower bound $\underline{\theta}_{1}:=-\infty$.

Suppose at iteration $k \geq 1$ of the solver, the following quantities are available: $z^{*}$ is an incumbent solution of (11), $\hat{z}^{k} \in \mathbb{R}_{+}^{n}$ and $\hat{u}^{k} \in \mathbb{R}_{+}^{m}$ are tentative primal and chal solutions
of the LP relaxation, and $\underline{\theta}_{k}$ is a lower bound on $\theta_{*}=v_{L P}(\mathrm{cf} .(6))$. If $e z^{*}=\left\lceil\underline{\theta}_{k}\right\rceil$, the solver may stop (since $z^{*}$ is optimal). Otherwise, for iterations $k$ specified below, the remaining heuristics consist in calling an extension of Procedure 1 with a copy of Step 4 inserted after Step 1; the sequential heuristics employed at these steps are listed below.

Our periodic heuristic Hl is called by the solver every twentieth iteration, starting from iteration $k=m+1$ (i.e., for $k=m+1, m+21, \ldots$ ), with the current relaxed solution $\hat{z}:=\hat{z}^{k}$ and the lower bound $\underline{\theta}_{k} \leq \theta_{*}$. H1 employs FFD in Procedure 1, exiting if $e z^{*}=\left\lceil\underline{\theta}_{k}\right\rceil$.

Our final heurstics H2, H3 and H4 are called successively upon termination of the solver, using the final $\hat{z}:=\hat{z}^{k}, \hat{u}:=\hat{u}^{k}$ and $\underline{\theta}_{k}$. H2 employs both FFD and SHP, H3 just SHP and the modified Step 3', whereas H4 uses SVC. Of course, H3 and H4 (or just H4) are not called if H2 (or H3) exits with $e z^{*}=\left\lceil\underline{\theta}_{k}\right\rceil$, whereas SVC exits when $e \bar{z}+e \tilde{z}=\left\lceil\underline{\theta}_{k}\right\rceil$. The impact of the varions heuristics will be discussed in §5.7.

## 4. The inexact proximal bundle method

We now sketch the main features of the inexact bundle method of Kiwiel (2006a).
Our method generates trial points $u^{k} \in \mathbb{R}_{+}^{m}, k=1,2, \ldots$, at which the dual function $\theta$ is cvaluated (possibly inexactly) as described in §2.2. Specifically, for each $k$, set $p^{k}$ to the (powsil)ly inaccurate) KP solution $p$ satisfying the bounds of (10) for $u=u^{k}$, and let $\zeta_{k}:=\zeta$, $\vec{\zeta}_{k}:=\bar{\zeta}$. Recalling (3), define the associated Lagrangian solution $z^{k}$ by setting

$$
z_{q}^{k}:=0 \text { for } q \neq p^{k}, \quad z_{p^{k}}^{k}:= \begin{cases}N & \text { if } \zeta_{k}>1,  \tag{16}\\ 0 & \text { otherwise. }\end{cases}
$$

Thus we have the lower bound $\underline{\theta}\left(u^{k}\right) \leq \theta\left(u^{k}\right)$ and $L\left(z^{k} ; u^{k}\right)=\bar{\theta}(u)$ in (10); in particular,

$$
\begin{equation*}
L\left(z^{k} ; u^{k}\right)-\theta\left(u^{k}\right) \leq N\left(\bar{\zeta}_{k}-\zeta_{k}\right) \leq N \epsilon_{r} \bar{\zeta}_{k} . \tag{17}
\end{equation*}
$$

Further, by (3), the following linearization of $\theta$ at $u^{k}$ majorizes $\theta(u)$ for all $u$ :

$$
\theta_{k}(u):=L\left(z^{k} ; u\right)=u d+ \begin{cases}N\left(1-u p^{k}\right) & \text { if } z^{k} \neq 0  \tag{18}\\ 0 & \text { otherwise }\end{cases}
$$

Iteration $k$ uses the polyhedral cutting-plane model of $\theta$

$$
\begin{equation*}
\hat{\theta}_{k}(\cdot):=\min _{j \in J^{k}} \theta_{j}(\cdot) \quad \text { with } \quad k \in J^{k} \subset\{1, \ldots, k\} \tag{19}
\end{equation*}
$$

for finding

$$
\begin{equation*}
u^{k+1}:=\arg \max \left\{\hat{\theta}_{k}(u)-\frac{1}{2 t_{k}}\left|u-\hat{u}^{k}\right|^{2}: u \in \mathbb{R}_{+}^{m}\right\} \tag{20}
\end{equation*}
$$

where $t_{k}>0$ is a stepsize that controls the size of $\left|u^{k+1}-\hat{u}^{k}\right|$ and the prox center $\hat{u}^{k}:=u^{k^{k}}$ has the value $\theta_{\hat{u}}^{k}:=\theta_{k^{\prime}}\left(u^{k^{\prime}}\right)$ for some $k^{\prime} \leq k$ (usually $\theta_{\hat{u}}^{k}=\max _{j=1}^{k} \theta_{j}\left(u^{j}\right)$ ). Due to evaluation errors, we may have $\theta_{i k}^{k}>\hat{\theta}_{k}\left(\hat{u}^{k}\right)$, in which case the predicted increase

$$
\begin{equation*}
v_{k}:=\hat{\theta}_{k}\left(u^{k+1}\right)-\theta_{\hat{u}}^{k} \tag{21}
\end{equation*}
$$

may be nonpositive; then $t_{k}$ is increased and $u^{k+1}$ is recomputed to increase $\hat{\theta}_{k}\left(u^{k+1}\right)$ until $v_{k} \geq\left|u^{k+1}-\hat{u}^{k}\right|^{2} / 2 t_{k}$. An ascent step to $\hat{u}^{k+1}:=u^{k+1}$ with $k^{\prime}:=k+1$ occurs if

$$
\begin{equation*}
\theta_{k+1}\left(u^{k+1}\right)-\theta_{\hat{u}}^{k} \geq \kappa v_{k} \tag{22}
\end{equation*}
$$

for a fixed $\kappa \in(0,1)$ (we use $\kappa=0.1$ ). Otherwise, a null step $\hat{u}^{k+1}:=\hat{u}^{k}$ improves the next model $\hat{\theta}_{k+1}$ with the new linearization $\theta_{k+1}$ as stipulated in (19).

If we omitted the quadratic term in (20), the resulting cutting-plane method could generate $u^{k+1}$ far from the previous points, and it would require storing all linearizations ( $J^{k}=\{1, \ldots, k\}$ in (19)). In contrast, the quadratic term usually keeps $u^{k+1}$ close enough to the best point found so far, and it allows limiting the number of stored linearizations.

We solve subproblem (20) with the QP routine of Kiwiel (1994), which funds its multipliers $\left\{\nu_{j}^{k}\right\}_{j \in J^{k}} \subset \mathbb{R}_{+}$, also known as convex weights, such that $\sum_{j \in J^{k}} \nu_{j}^{k}=1$ and the set $\hat{J}^{k}:=$ $\left\{j \in J^{k}: \nu_{j}^{k} \neq 0\right\}$ has at most $m+1$ elements. We set $J^{k+1}:=J^{k} \cup\{k+1\}$ and then, if necessary, drop from $J^{k+1}$ an index $j \in J^{k} \backslash \hat{J}^{k}$ with the largest $\theta_{j}\left(\hat{u}^{k}\right)$ to keep $\left|J^{k+1}\right| \leq M$ for a fixed $M \geq m+2$.

Combining the accumnlated Lagrangian solutions $\left\{z^{j}\right\}_{j \in J^{k}}$ with their weights $\left\{\nu_{j}^{k}\right\}_{j \in J^{k}}$, we may estimate solutions to the LP relaxation of (2) via the aggregate primal solution

$$
\begin{equation*}
\hat{z}^{k}:=\sum_{j \in J^{k}} \nu_{j}^{k} z^{j} \tag{23}
\end{equation*}
$$

In other words (cf. (16)), $\hat{z}_{p^{j}}^{k}=N \nu_{j}^{k}$ for nontrivial patterns $p^{j}$ indexed by $J_{P}^{k}:=\left\{j \in \hat{J}^{k}\right.$ : $z^{\prime} \neq 0$ \} (which need not be stored, since they can be recovered from $\nabla \theta_{j}=d-N p^{j}$; see (18)). Our heuristics also use the lower bound $\underline{\theta}_{k}:=\max _{j \leq k} \underline{\theta}\left(u^{j}\right)$ on $\theta_{*}=v_{L P}$ (cf. (6)).

We now point out some useful consequences of the convergence analysis in (Kiwiel, 2006a, 45). The LP relaxation of (2) may be written as

$$
\begin{equation*}
v_{L P}:=\min \bar{\psi}_{0}(z):=\sum_{p \in P} z_{p} \text { s.t. } \bar{\psi}(z):=d-\sum_{p \in P} p z_{p} \leq 0, z \in \operatorname{conv} Z . \tag{24}
\end{equation*}
$$

Let $\epsilon:=\sup _{k}\left[\theta_{k}\left(u^{k}\right)-\theta\left(u^{k}\right)\right]$ be the maximum evaluation error; by (17), we have $\epsilon \leq \bar{\epsilon}:=$ $N \epsilon_{r} \sup _{k} \bar{\zeta}_{k}$. Consider the set of $\epsilon$-optimal solutions of the LP relaxation (24):

$$
\begin{equation*}
Z_{\epsilon}:=\left\{z \in \operatorname{conv} Z: \bar{\psi}_{0}(z) \leq v_{L P}+\epsilon, \bar{\psi}(z) \leq 0\right\} \tag{25}
\end{equation*}
$$

The limits $\theta_{\hat{i}}^{\infty}:=\lim _{k} \theta_{\bar{u}}^{k}, \underline{\theta}_{\infty}:=\lim _{k} \underline{\theta}_{k}$ satisfy $\theta_{u}^{\infty} \in\left[v_{L P}, v_{L P}+\epsilon\right], \underline{\theta}_{\infty} \in\left[\theta_{u}^{\infty}-\bar{\epsilon}, v_{L P}\right]$, and there exists $K \subset\{1,2, \ldots\}$ such that $\lim _{k \in K} \bar{\psi}_{0}\left(\tilde{z}^{k}\right)=\theta_{\tilde{u}}^{\infty}$ and $\overline{\lim }_{k \in K} \max _{i=1}^{m} \bar{\psi}_{i}\left(\hat{z}^{k}\right) \leq 0$; in particular, the bounded sequence $\left\{\tilde{z}^{k}\right\}_{k \in K}$ converges to the $\epsilon$-optimal set $Z_{\epsilon}$. If $\epsilon_{r}$ is snall enough, the accuracy observed in practice corresponds to such estimates with $\epsilon$ and $\bar{\epsilon}$ determined by the maximum errors $\theta_{k}\left(u^{k}\right)-\theta\left(u^{k}\right)$ and $\theta\left(u^{k}\right)-\underline{\theta}\left(u^{k}\right)$ that occur for large $k$; since both errors are at most $N\left(\bar{\zeta}_{k}-\zeta_{k}\right)$, where the KP gap $\bar{\zeta}_{k}-\zeta_{k}$ is usually tiny for large $h$, small values of $\epsilon$ and $\bar{\epsilon}$ can be attained if the algorithm runs long enough.

We stop if $\min \left\{v_{k},\left|\pi^{k}\right|+\alpha_{k}\right\} \leq \epsilon_{\text {opt }}\left(1+\left|\theta_{\hat{i} k}^{k}\right|\right)$, where $v_{k}$ is given by (21), $\pi^{k}:=\left(\hat{u}^{k}-\right.$ $\left.u^{k+1}\right) / t_{k}, \alpha_{k}:=v_{k}-t_{k}\left|\pi^{k}\right|^{2}$ and $\epsilon_{\text {opt }}>0$ is an optimality tolerance (cf. (Kiwiel, 2006a, §4.2)). For $\epsilon_{\text {opt }}=\epsilon_{r}=10^{-8}, \underline{\theta}_{k}$ usually agrees with $\theta_{*}$ in at least 8 digits, enough for our purposes.

## 5. Computational results

### 5.1. Data sets

In our computational experiments, for the CSP we use the 28 industrial instances of Vance (1998), the 10 industrial instances of Vanderbeck (1999), and the 20 industrial instances of Degraeve and Schrage (1999). In addition, we use the following randomly generated instances: the 4000 instances of Wäscher and Gau (1996), the 3360 instances of Degraeve and Peeters (2003) and the 120 instances of Vanderbeck (1909). For the BPP, we use the 540 randomly generated instances of Degraeve and Peeters (2003), and the 160 instances fiom the BINPACK collection of the OR-Library (Beasley, 1990).

The instances of Wäscher and Gau (1996) are constructed by the CUTGEN1 generator of Gan and Wäscher (1995), using the following parameter values; the number of orders $m=10,20,30,40,50$, the width $W=10,000$, the interval fraction $c=0.25,0.5,0.75,1$, and the average clemand $\bar{d}=10,50$. The widths $w_{i}$ are uniformly distributed integers between 1 and $c W^{\prime}$. For $m$ uniform random numbers $R_{1}, \ldots, R_{m} \in(0,1)$, the demands $d_{i}:=\left\lfloor\frac{R_{2} m \bar{d}}{R_{1}+\cdots+R_{i m}}\right\rfloor$ for $i<m$, and $d_{m}:=m \bar{d}-\sum_{i<m} d_{i}$ (in fact slightly more complicated formulas are used by Gau and Wäscher (1995)). Duplicate widths are aggregated by summing their demands.

Combining the different values for $m, c$ and $\bar{d}$ results in 40 classes; in each class, 100 instances are generated.

The small-item-size instances of Degraeve and Peeters (2003) are generated similarly for $m=10,20,30,40,50,75,100, c=0.25,0.5,0.75,1$ and $\bar{d}=10,50,100$, except that $R_{1}, \ldots, R_{m} \in(0.1,0.9)$ for the demand distribution. In the medium-item-size instances of Degraeve and Peeters (2003), only $\bar{d}=50$ is used and the widths are uniformly distributed on $\left[w_{\text {min }}, \mathrm{cW}\right]$, where $w_{\text {min }}=500,1000,1500$. Both cases have 84 data classes, and 20 instances are generated in each class.

The instances of Vanderbeck (1999) comprise 6 classes with $m=50$, and 20 instances per class. The first three classes are generated like those of Wäscher and Gau (1996) above with $c=0.25,0.5,0.75$ and $\bar{d}=50$, the next two classes have widths in $[500,2500]$ and $[500,5000]$ with $\bar{d}=50$, and the sixth class has widths in $[500,5000]$ and $\bar{d}=100$.

In the BPP instances of Degraeve and Peeters (2003), $m=500$ or 1000 weights are uniformly distributed in the intervals $[1,100],[20,100],[50,100]$ as in BPPGEN (Scliwerin and Wäscher, 1997), and the capacity $W=100,120,150$; identical items are aggregated for the corresponding CSPs. In each of the 18 resulting classes, 20 instances are generated. The modified BPP instances of Degraeve and Peeters (2003) use $m=500$, the weight intervals [1, 10000], [2000, 10000], [5000, 10000], and the capacity $W=10000,12000,15000$, again with 20 instances per class.

The BINPACK instances from the OR-Library (Beasley, 1990) comprise two categories. The uniform category has the capacity $W=150, m$ weights uniformly distributed in the interval $[20,100]$, and 20 instances generated for each value of $m=120,250,500,1000$. (The classes with $m=500,1000$ also appear in the BPP category of Degraeve and Peeters (2003), but with different instances.) In the triplet catcgory, each bin of capacity $W=1000$ is filled with exactly three items (the first item $w^{\prime}$ is picked in [380,490], the second item $w^{\prime \prime}$ in $\left[250,\left(W-w^{\prime}\right) / 2\right)$, and the third item equals $\left.W-w^{\prime}-w^{\prime \prime}\right)$. There are 20 instances for each value of $m=60,120,249,501$.

### 5.2. Implemented variants

Our codes were programmed in Fortrau 77 and rum on a notebook PC (Pentium M 7552 $\mathrm{GHz}, 1.5 \mathrm{~GB}$ RAM) under MS Windows XP.

For solving the dual problem (6), we used a general-purpose bundle code that treats subgradients as dense vectors in double precision. A faster code could exploit the fact that

Table 1: Small-item-size instances of Degraeve and Peeters (2003), int $=$ all, $\bar{d}=$ all

| $m$ | $m_{\mathrm{av}}$ | $n_{\mathrm{av}}^{\prime}$ | $i_{\mathrm{av}}$ | $i_{\mathrm{mxx}}$ | $t_{\mathrm{av}}$ | $t_{\mathrm{mx}}$ | $n_{e}$ | H 1 | H 2 | H 3 | H 4 | $n_{\mathrm{g}}$ |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| 10 | 9.99 | 26.77 | 15.14 | 31 | 0.00 | 0.01 | 113 | 49 | 70 | 1 | 0 | 0 |
| 20 | 19.95 | 53.13 | 32.51 | 69 | 0.01 | 0.04 | 120 | 64 | 64 | 0 | 0 | 0 |
| 30 | 29.91 | 79.76 | 51.90 | 91 | 0.02 | 0.22 | 130 | 85 | 57 | 0 | 0 | 1 |
| 40 | 39.85 | 105.55 | 70.41 | 134 | 0.04 | 0.36 | 134 | 98 | 53 | 0 | 0 | 0 |
| 50 | 49.75 | 132.16 | 90.20 | 181 | 0.08 | 0.66 | 134 | 102 | 55 | 0 | 0 | 0 |
| 75 | 74.36 | 197.32 | 141.82 | 256 | 0.24 | 2.00 | 149 | 122 | 43 | 0 | 0 | 0 |
| 100 | 98.92 | 263.36 | 183.88 | 311 | 0.40 | 2.81 | 165 | 136 | 34 | 0 | 1 | 0 |

each subgradient of $\theta$ has the form $\nabla \theta_{k}=d$ or $\nabla \theta_{k}=d-N p^{k}$ (see (18)), with a common integer part $d$ and an integer sparse knapsack solution $p^{k}$. Ignoring sparsity, our code requires $m \times M$ memory locations for storing up to $M \geq m+3$ subgradients, and additional workspace of order $M^{2}$ for solving the QP subproblem (20) with the routine of Kiwiel (1994). We used $M=m+3$ to test how "minimal" bundle performs.

The bounded KPs arising in column generation and SHP were solved by the modified version of MT1R (cf. §2.2) with the accuracy tolerance $\epsilon_{r}=10^{-5}$ (other choices are discussed in §5.6.2); MT1R's tolerance $\epsilon$ was set to $10^{-12}$. For column generation, we used the relaxed bounds of (9), because the tighter bounds of (8) produced longer computing times. In contrast, SHP employed in (14) the natural bounds given by (8) with $d$ replaced by $d^{\prime \prime}$.

Our implementation of the rounding procedure of $\S 3.1$ is slower than necessary because the patterns are recovered as $p^{j}=\left(d-\nabla \theta_{j}\right) / N$, instead of being stored separately.

### 5.3. Results for the cutting-stock problem

To ease comparisons, we follow closely the presentation of Degraeve and Peeters (2003). Every data class is identified by three parameters: the number of items $m$, the interval in which the widths are distributed denoted by int, and the average demand $\bar{d}$. An indicator "all" for any of these parameters means that the reported results are aggregated over all relevant values for that particular parameter. If a parameter is constant for all instances represented in a table, its value is indicated in the table heading.

Our results for the small-item-size instances of Degraeve and Peeters (2003) with int =all, $\bar{d}=$ all are reported in Table 1; full details are given in Tables 9-11 in the Online Supplement to this paper on the journal's website. The columns $m_{\mathrm{av}}$ and $m_{\mathrm{av}}^{\prime}$ give the average numbers of items and variables in the associated $0-1$ knapsack subproblems. The columns $i_{\mathrm{av}}$ and $i_{\mathrm{mx}}$

Table 2: Medium-item-size instances of Degraeve and Peeters (2003), int $=$ all, $\bar{d}=50$

| m | $m_{\text {av }}$ | $m_{\text {av }}^{\prime}$ | $i_{\text {av }}$ | $i_{\text {mix }}$ | $t_{\text {av }}$ | $t_{\text {mix }}$ | $n_{e}$ | H1 | H2 | H3 | H4 | $n_{g}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| 30 | 29.84 | 68.47 | 53.71 | 93 | 0.02 | 0.16 | 73 | 73 | 105 | 0 | 0 | 0 |
| 40 | 30.78 | 90.65 | 69.94 | 120 | 0.03 | 0.58 | 70 | 63 | 110 | 0 | 0 | 0 |
| 50 | 49.64 | 113.69 | 88.76 | 156 | 0.06 | 0.90 | 74 | 65 | 118 | 1 | 1 | 1 |
| 75 | 74.08 | 169.10 | 137.04 | 232 | 0.37 | 8.60 | 82 | 73 | 105 | 0 | 0 | 1 |
| 100 | 98.45 | 226.07 | 184.45 | 295 | 1.43 | 62.18 | 73 | 72 | 117 | 0 | 4 | 0 |

report the average and maximum numbers of iterations of the bundle code. The columns $t_{\mathrm{av}}$ and $t_{n x}$ give the average and maximum rumning times in wall-clock seconcls. The column $n_{e}$ lists the numbers of "early" terminations due to discovering that $e z^{*}=\left\lceil\underline{\theta}_{k}\right\rceil$ for the incumbent $z^{*}$ delivered by H 0 or H 1 before bundle terminated on its own. Recall that H 1 is called after $\mathrm{H} 0, \mathrm{H} 2$ after H 1 , etc., unless $e z^{*}=\left\{\underline{\theta}_{k}\right\}$ occurs earlier. The columns labelled H1 through H4 give the numbers of instances in which the corresponding heuristic found the best primal value $e z^{*}$ first (for the remaining instances $e z^{*}$ was found by H0); a zero entry means that heuristic was not called or did not contribute usefully. The final column $n_{g}$ reports the numbers of instances with a nonzero final gap $g:=e z^{*}-\left\lceil\underline{\theta}_{k}\right\rceil$; we stress that the final gaps never exceeded one unit in all of our instances. The averages, maxima and sums in Table 1 are taken over the 240 instances used for each value of $m$.

From the entries for $n_{e}$, H1 through H 4 and $n_{g}$ in Table 1, we see that early termination occured on between $47 \%$ and $69 \%$ of problems, H 0 and H1 solved between $70 \%$ and $85 \%$ of problems, H 2 solved almost all the remaining problems, H3 and H4 helped in solving 2 problcms, and just one out of the 1680 problems was not solved. Note that the best method LR of Degraeve and Peeters (2003) also could not solve one instance within 15 minutes (two instances within 6 minutes), and its FFD-based rounding heuristic solved $91.6 \%$ of problems, whereas our "lighter" heuristics H0 through H2 solved $99.8 \%$ of problems.

Our results for the medium-item-size instances of Degraeve and Peeters (2003) are presented in Table 2, where each row gives statistics over the 240 instances used for each value of $m$ (see Tables 12 and 13 for more details). Early termination occured on between $22 \%$ and $35 \%$ of problems, H 0 and H 1 solved between $49 \%$ and $56 \%$ of problems, H 2 solved almost all the remaining problems, H 3 solved one problem, H 4 solved 7 problems, and just two out of the 1680 problems were not solved. The rounding heuristic of Degraeve and Peeters (2003)

| 100 | [500, 5000] | 49.70 | 129.25 | 104.40 | 131 | 0.14 | 0.32 | 8 | 8 | 12 | 0 | 0 | 0 |

solved $69.9 \%$ of problems, whereas H0 through H2 solved $99.4 \%$ of problems.
Comparing Tables $I$ and 2 , we see that the average and maximum solution times are quite similar in the small- and medium-size-item cases for problem sizes $m$ up to 50 . However, for $m=75$ and 100 , in the medimm-size-item case the average solution times grow significantly, and the nraximum solution times jump up, most spectacularly on the instances with width interval $[1500,2500]$; see Table 13. This is due to the poor performance of our kuapsack solver on these instances. Similar slowdowns on this interval were reported in (Degraeve and Peeters, 2003, Tab. 4a) already for $m=20$, i.e., even for smaller problems.

To save space, Table 3 presents only aggregate results on the instances of Wäscher and Gau (1996), with each row giving statistics over the 800 instances used for each value of $m$. Here our main point is that only three out of $4000(0.075 \%)$ problems were not solved. Our "lighter" heuristics H0 through H2 solved $99.7 \%$ of problems, whereas the two best. (and more complicated) heuristics RSUC and CSTAOPT of Wäscher and Gau (1996) solved $98.0 \%$ and $92.7 \%$ of problems, respectively ( $99.6 \%$ if they had been applied together). The fairly large maximum solution time in Tab. 3 stemmed from a single knapsack subproblem.

Table 4 gives our results for the 6 data classes of Vanderbeck (1999) with $m=50$ and 20 instances per row. Since we used the original instances, the results are not identical to those

Table 5: BPP instances of Degraeve and Peeters (2003)

in Tabs. 9 and 13, but the performance of H 0 through H 2 is similar; in fact H 0 througl H 2 suffice for solving all the CSP instances used by Vanderbeck (1999).

Quite suprisingly, all the industrial instances we could find in the literature turned out to be easy for our method: they were solved in a fraction of a second (see Tables 14-16).

### 5.4. Results for the bin-packing problem

Following Degraeve and Peeters (2003), in the next three tables we present our results for the BPP. Table 5 gives our results for the BPP instances of Degraeve and Peeters (2003) (20 instances per row). All the 360 instances were solved (H4 helped once).

Table 6 reports results for the BINPACK instances from the OR-Library (Beasley, 1990) (20 instances per row). The first four uniform classes were solved by calling H4 just once. However, only 19 out of the 80 triplet instances were solved (with H 4 helping on one instance). The remaining instances had unit gaps; the "gap" column gives averages of relative gaps (ez* $-\left\lceil\underline{\theta}_{k}\right\rceil$ )/ $\left\lceil\underline{\theta}_{k}\right\rceil$. We add that for the CSP instances of $\S 5.3$, the ruming times of H 4 were not excessive, and H 4 was called quite infrequently anyway. In contrast, on the triplet classes t 249 and t 501 , the use of H 4 increased the ruming times substantially, as illustrated in Table 7 (the influence of H 3 could be ignored). Note that the triplet classes are quite difficult for traditional LP relaxation (Degraeve and Peeters, 2003, Tab. 12).

Table 8 presents our results for the modified BPP classes of Degraeve and Peeters (2003) (20 instances per row as described in $\S 5.1$ ). Just one out of the 180 problems was not solved (H4 helped on one problem). The transformation into a CSP reduced the number of items by at most $5 \%$ on average. For almost 500 variables, the large iteration numbers and running times are not too suprising.

Figure 1: Performance profile for inexact bundle with tight vs. relaxed bounds

### 5.5. Impact of tighter knapsack bounds

The results of $\$ 5.3$ were obtained for the relaxed bounds of (9). Using the tighter bounds of ( 8 ) allowed us to solve just two more instances at the expense of longer rumning times (see Tabs. 17-19). To save space, from now on we employ the standard set of the 7360 instances from Tabs. 1-3 to evaluate our heuristics, and its reduced subset with $m \geq 30$ (4800 instances) for performance profiles (Dolan and Moré, 2002), with zero ruming times replaced by 0.001 due to the poor resolution of our timer. The performance profile of tighter vs. relaxed bounds is given in Fig 1 ; it plots the portion of instances $\rho_{s}(\tau)$ on which a particular variant was not slower than the fastest variant by more than a given ratio $\tau$.

### 5.6. Impact of evaluation errors

### 5.6.1. Comparison with exact bundle

When the dual objective evaluations happen to be exact, our code runs essentially like the standard bundle of Feltemmark and Kiwiel (2000). Figure 2 gives the performance profile of inexact bundle ( $\epsilon_{r}=10^{-5}$ ) with relaxed bounds vs. exact bundle ( $\epsilon_{r}=0$ ) with relaxed or tighter bounds. Referring to Tabs. 22-27 for details, we only note that the ruming times increased quite dramatically (usually at least 30 times) in the exact case, although the iteration numbers and the performance of our heuristics did not change significantly.

Figure 2: Performance profile for inexact bundle with relaxed bounds vs. exact bundle with tight/relaxed bounds

Figure 3: Performance profile for relative error tolerances

### 5.6.2. Other choices of the relative error tolerance

In the initial version of this paper we used the accuracy tolerance $\epsilon_{r}=10^{-8}$; the results were very close to those in Tabs. 1-18 (where $\epsilon_{r}=10^{-5}$ ). Figure 3 gives the performance profile for $\epsilon_{r}=10^{-5}, 10^{-4}$ and $10^{-3}$ (see also Tabs. 28-33). Here $\epsilon_{r}=10^{-4}$ did not improve on our standard cloice of $\epsilon_{r}=10^{-5}$ (giving one more gap in Tab. 28), whereas $\epsilon_{r}=10^{-3}$ was too large, cansing ulu heuristics to fail more frequently ( 168 more gaps in Tabs. 31--33).

Further insight may be gained as follows. By (10), the absolute error in evaluating $A$ is bounded by $N \epsilon_{1}$, once $\bar{\zeta}$ gets close to 1 . The upper bound $N:=e z^{*}$ delivered by FFD (cf. §3.3) is usually close to the optimal primal value $v_{*}$. Typical instances have the integer

Figure 4: Performance profile for absolute error tolerances

round-up property $\left\lceil\theta_{*}\right\rceil=v_{*}$, but our heuristics fail if we can't find a lower bound $\underline{\theta}_{k}>v_{*}-1$. Thus we may expect failures when the absolute errors get close to $N \epsilon_{r}>1$. Now, in Tables 31-33 the average values of $v_{*}$ and $N$ grow linearly with $m_{1}$, reaching order 5000,2875 and 1250 for the final classes, where $N \epsilon_{r}>1$ for $\epsilon_{r}=10^{-3}$; thus the small percentage of failures suggests that the actual errors tended to be smaller than their upper bounds.

### 5.6.3. Absolute error tolerances

In view of the discussion in $\S 5.6 .2$, we also considered choosing $\epsilon_{r}$ so that the evaluation errors did not exceed a given absolute error tolerance $\epsilon_{a}<1$ (with SHP using $\epsilon_{r}=10^{-5}$ as in 5.3). Specifically, for evaluating $\theta$ we used $\epsilon_{r}:=\epsilon_{n} / N$. Figure 4 gives the performance profile for $\epsilon_{n}=0.01$ and 0.05 vs . the standard $\epsilon_{r}=10^{-5}$ (see also Tabs. 34-39). Our results for $\epsilon_{n}=0.01$ were very close to those for $\epsilon_{r}=10^{-5}$, whereas $\epsilon_{a}=0.05$ was too large, causing our heuristics to fail more frequently (16 more gaps in Tabs. 37-39).

### 5.6.4. More inexact null steps

We now consider a modification in which our KP solver exits once at least bkmin backtrackings have occured, for a given parameter bkmin, and the incumbent value $\zeta$ satisfies

$$
\begin{equation*}
\zeta>1+\left(u^{k+1} d-\theta_{\bar{u}}^{k}-\kappa v_{k}\right) / N, \tag{26}
\end{equation*}
$$

so that $\zeta_{k+1}:=\zeta$ yields a null step; cf. (22) (normally $u^{k+1} d>\theta_{\hat{u}}^{k}+\kappa v_{k}$ and (26) holds iff (22) fails). Such "more inexact" null steps may save KP work, but shallower cuts may

Figure 5: Performance profile for bkmin

yield slower convergence; see (Kiwiel, 2006b, §4.2) for a general discussion of relaxed mull steps. Figure 5 gives the performance profile for bkmin $=0,1000$ and $\infty$ with $\epsilon_{r}=10^{-5}$ (see also Tabs. 40-45). Relative to the standard bkmin $=\infty$, for bkmin $=0$ the average iteration numbers grew by $59-114 \%$ on the largest instances, and four more gaps occured. In contrast, for bkmin $=1000$ the average iteration numbers grew by only $5-13 \%$ on the largest instances, the solution times decreased noticeably, and three gaps disappeared. On the other hand, the maximum iteration numbers increased substantially on the larger instances, giving some cause for concern.

### 5.6.5. A discussion of error tolerances

Although in general one may expect tradeoffs between the accuracy of subproblem solutions and the speed of convergence, for the CSP such tradeoffs may have little practical impact, since Tables $9-30$ exhibit fairly small variations in iteration numbers and computing times for "reasonable" accuracy tolerances. Therefore, we would not expect much gain from dynamic tolerance adjustment: loose at the begiming and progressively decreasing.

We add that dynamic handling of the accuracy may be important in general, especially if the oracle's work depends "continuously" on the accuracy required. However, this need not be the case for our MT1R, which seems to lave the following properties: (1) its work explodes on some subproblems when the accuracy required is "too high"; and (2) its work does not vary much otherwise. Thus the main point is to avoid accuracies that are "too high", or "too low" for the dual solver to succeed, whereas for all "intermediate" accuracies, the solution
time should not vary significantly (unless smaller accuracies affect the iteration numbers "more than proportionally"). We conjecture that similar effects are likely to hold for other integer-progranming applications with branch-and-bound oracles that deliver relatively good incumbents quickly.

### 5.7. Impact of various heuristics

For the 7,538 CSP instances reported in Tabs. 1-4 and 14-16, our heuristics H3 and H4 helped in solving 3 and 21 problems, respectively, and 6 problems were not solved. When H3 was switched off, H 4 solved the three instances previously solved by H 3 , with the same timings. Thus H 3 could be onitted, but it might become more useful on other instances. On the other hand, it is worth observing that when both H 3 and H 4 were switched off, our "lighter" heuristics H1 and H2 performed quite well, solving $99.64 \%$ of problems.

In an attempt to assess the importance of the combination of oversupply reduction (Step 2 of Procedure 1), rounding up (Step 3), and residual problem extension (Step 5), we tested a version of the residual rounding heuristic named H5 that simply rounds the final relaxed primal solution down, and performs FFD on the residual problem to angment the rounded down solution. With Steps 2, 3, and 5 of the rounding procedure omitted, this heuristic H5 was able to optimally solve only $87.01 \%$ of the standard instances, as opposed to $99.64 \%$ for the default implementation of H0, H1 and H2 (see Tabs. 46-48). Thus these steps (in tandem) are very important to its overall success.

Our next improvement on H5, named H6, consists in calling Procedure 1 with only Step 2 unitted, and Step 4 using FFD. H6 performs much better than H5, solving $96.00 \%$ of problems (see Tabs. 49-51). Thus the rounding procedure of Belov and Scheithatuer (2002) may yield significant improvements also for FFD.

Finally, we note that H2 and H4 improve on H6 by using Step 2 of Procedure 1 and either SHP or SVC in addition to FFD at Step 4. Specifically, H1 and H2 solved $99.64 \%$ of problems, and together with H 4 they solved $99.92 \%$ of problems. To save space, the results for H 2 alone are omitted.

### 5.8. Comparisons with other procedures from the literature

In view of (5)-(6), our algorithm may be regarded as an exact penalty method for the constrained problem of maximizing $u d$ s.t. $u p(u) \leq 1, u \geq 0$. This problem can also be

Figure 6: Performance profile for conic vs. penalty bundle

solved by the conic variant of Kiwiel and Lemaréchal (2007). Figure 6 gives the performance profile for the conic vs, penalty variant. The conic variant was slightly slower, and gave one more gap on the standard set; cf. Tabs. 52-54.

The comparison in (Kiwiel and Lemaréchal, 2007, §7.4) of the conic variant with the procedures of Degraeve and Peeters (2003) in terns of the numbers of oracle calls carries over to the penalty variant as well, since both variants behaved similarly. Although proper timing comparisons are not available, Table 55 in the supplement suggests that our code may compete with the procedures of Degraeve and Peeters (2003), at least on some instances.

Finally, we add that Table 60 in the supplement shows that our standard variant (with $\epsilon_{r}=10^{-5}$ and relaxed bounds) is much faster than the algorithms tested in (Briant et al., $2007, \S 2.2$ ), with speedups of at least 8 for the smallest instances, and of order 11-90 for the larger instances.

## 6. Conclusions

For cutting-stock problems, we have shown that an inexact bundle approach to solving the LP relaxation, coupled with rounding heuristics, is a method that is able to effectively solve many cutting-stock instances from the literature. By solving the KP subproblems only to a relative accuracy of $\epsilon_{r}=10^{-5}$ we get (almost uniformly) speedup of the order of at least 30 in average on larger instances. Although our heuristics combine several well-known ideas from the literature, our two "lighter" heuristics H1 and H2 performed suprisingly well, solving
$99.64 \%$ of standard test problems, and together with our "heavier" heuristic H 4 they solved $99.92 \%$ of problems.

## Acknowledgments

I would like to thank the Associate Editor and the two anonymous referees for helpful comments. Further, I am grateful to G. Belov, Z. Degraeve, M. Peeters, D. Pisinger', G. Scheithauer and L. Schrage for extensive discussions, and F. Vanderbeck and G. Wäscher for sharing their instances. Special thanks go to C. Lemaréchal for inspiring this work. This research was supported by the INRIA New Investigation Grant "Convex Optimization and Dantzig-Wolfe Decomposition".

## A. Additional tables

## A.1. Results for the cutting-stock problem

Tables 9-11 below give details for the small-item-size instances of Degraeve and Peeters (2003). The averages, maxima and sums in Table 9 are taken over 20 instances for each interval, and thus over 80 instances for each "all" row. In Table 10, there are 60 instances per interval (i.e., 20 instances for each value of the average demand $\bar{d}=10,50,100$ ), and each "all" row gives statistics over the 240 instances used for each value of $m$. Finally, each row in Table 11 reports statistics over 80 instances (obtained from the 20 instances used for each of the four width intervals).

Our detailed results for the medium-item-size instances of Degraeve and Peeters (2003) are presented in Tables 12 and 13 , where each "all" row gives statistics over the 240 instances used for each value of $m$.

Tables 14-16 give our results for the industrial instances of Vance (1998) (as numbered in (Degraeve and Peeters, 2003, Tab. 7)), (Vanderbeck, 1999, Tab. 1) and Degraeve and Schrage (1999) (as named in (Degraeve and Peeters, 2003, Tab. 9)). The final column identifies the heuristic which delivered the optimal solution; in other words, H0 through H2 solved all these instances except for a single instance solved by H 3 .

## A.2. Impact of tighter knapsack bounds

The following tables and remarks list only data classes on which the tightening of KP bounds (using (8) instead of (9)) mattered most, giving more details for larger problem sizes.

Concerning Tables 17-18, the good news is that tighter bounds allowed us to solve all the snall-item-size instances of Degraeve and Peeters (2003), and all but one of the medium-item-size instances of Degraeve and Peeters (2003). Unfortunately the running times grew substantially relative to Tabs. 1-2. On the small-item-size instances, for $m \geq 40$ the average ruming times grew by about $150 \%$; on the medium-item-size instances, the average running times grew by $200 \%, 217 \%, 303 \%$ and $446 \%$ for $m=40,50,75$ and 100 (see Tabs. $20-21$ for more details). The iteration numbers were about the same. The increase in runing times can be attributed to the knapsack solver (which made more than two million backtrackings

Table 20: Small-item-size instances with tight KP bounds, $\bar{d}=$ all

| $m$ | int | $m_{\mathrm{av}}$ | $\boldsymbol{m}_{\mathrm{av}}^{\prime}$ | $\boldsymbol{i}_{\mathrm{av}}$ | $\boldsymbol{i}_{\mathrm{mx}}$ | $t_{\mathrm{av}}$ | $t_{\mathrm{mx}}$ | $\boldsymbol{n}_{\boldsymbol{e}}$ | H 1 | H 2 | H 3 | H 4 | $n_{g}$ |

|  | $[1,10000]$ | 99.45 | 191.37 | 225.10 | 301 | 0.51 | 1.68 | 16 | 9 | 11 | 0 | 1 | 0 |
|  | all | 98.92 | 263.36 | 183.75 | 319 | 0.88 | 11.15 | 153 | 125 | 45 | 0 | 1 | 0 |

on some sulbproblems).
Tables 20-21 complement Tables 17-18. Relative to Tabs. 10 and 13 , on the small-itemsize instances, for $m \geq 40$ the average running times grew mostly from increasing by about $200 \%$ on width interval $[1,5000]$. On the medium-item-size instances, the average running times increased by $367-531 \%$ on width interval [ 1500,2500 ], $157-223 \%$ on [ 500,5000 ], and $140-179 \%$ on $[1000,5000]$; for $m=100$, they went up by $67-156 \%$ on four other intervals. The iteration numbers were about the same.

For the instances of Wäscher and Gau (1996) in Tab. 19, the same 3997 out of 4000 instances were solved, but relative to Tab. 3, for $m=40$ and 50 the average running times grew by $100 \%$ and $143 \%$.

For the instances of Vanderbeck (1999), relative to Tab. 4, the average running times grew by between $67 \%$ and $205 \%$; their sum increased by $175 \%$.

## A.3. Impact of evaluation errors

## A.3.1. Comparison with exact bundle

Tables 22-24 summarize our results for exact KP solutions ( $\epsilon_{r}=0$ ) relative to Tabs. 1-3 (where $\epsilon_{\tau}=10^{-5}$ ); similar features were observed on other instances. First, the iteration numbers and the performance of our heuristics did not change significantly. (In other words, the errors occuring in the inexact case were small enough to be accomnodated gracefully by our code.) Second, the running times increased quite dramatically. For instance, in Tab. 22 relative to Tab. 1 , for $m=30,40,50,75$ and 100 , the average times grew by factors of 27.5 , $75.8,13.5,29.0$ and 34.9 , respectively; in Tab. 23 relative to Tab. 2, the factors are 33.5, $112.0,28.8,83.3$ and 47.1; in Tab. 24 relative to Tab. 3, for $m=30,40$ and 50 the factors are $43.0,40.0$ and 44.7. Thus the speedup of inexact bundle ( $\epsilon_{r}=10^{-5}$ ) w.r.t. exact bundle

is (almost uniformly) of order at least 30.
Tabs. 1-3 and 22-24 were obtained for the relaxed bounds of (9). Using the tighter bounds of (8) in exact bundle produced Tabs. 25-27. Here note that, in contrast with inexact bundle which for tighter bounds became at least twice slower on the larger instances (cf. §A.2), the average running times of exact bundle with tighter bounds usually did not increase so much (and sometimes even decreased). Specifically, in Tab. 25 relative to Tab. 22 , for $m=30,40,50,75$ and 100 , the average tinies grew by factors of $1.1,1.0,1.0,3.6$ and 1.5, respectively; for Tab. 26 relative to Tab. 23, the factors are 1.0, 0.9, 1.4, 1.2 and 1.1; in Tab. 27 relative to Tab. 24, for $m=30,40$ and 50 the factors are $0.5,1.1$ and 0.74 .

Hence, the speedups of inexact bundle with relaxed bounds against exact bundle with relaxed or tighter bounds were similar. Indeed, in Tab. 25 relative to Tab. 1, for $m=$
$30,40,50,75$ and 100 , the average times grew by factors of $31.5,74.2,13.7,104.4$ and 53.2 , respectively; for Tab. 26 relative to Tab. 2, the factors are 33.5, 99.3, 39.5, 98.2 and 51.3 ; in Tab. 27 relative to Tab. 3, for $m=30,40$ and 50 the factors are $23.0,43.1$ and 33.0.

## A.3.2. Other choices of the relative error tolerance

In parallel with Tabs. 22-24, Tables 28-33 give results for $\epsilon_{r}=10^{-4}$ and $10^{-3}$. The average iteration numbers and computing times were similar for $\epsilon_{\tau}=10^{-5}, 10^{-4}$ and $10^{-3}$. However, $\epsilon_{r}=10^{-3}$ was too large, causing our heuristics to fail more frequently. On the other hand, $\epsilon_{r}=10^{-4}$ did not improve on our standard choice of $\epsilon_{r}=10^{-5}$ (giving one nore gap in Tab. 28).

## A.3.3. Absolute error tolerances

Tables 34-39 give results for $\epsilon_{a}=0.01$ and 0.05 . For both values of $\epsilon_{a}$, the average iteration numbers and computing times were close to those in Tabs. 1-3 (where $\epsilon_{r}=10^{-5}$ ). However, $\epsilon_{a}=0.05$ was too large, causing our heuristics to fail more frequently. On the other hand, our results for $\epsilon_{a}=0.01$ were very close to those for $\epsilon_{r}=10^{-5}$.

## A.3.4. More inexact null steps

Tables $40-45$ give results for bkmin $=0$ and 1000 (with $\epsilon_{r}=10^{-5}$ ). Relative to Tabs. 1-3, where bkmin $=\infty$, for bkmin $=0$ the average iteration numbers grew by $59-114 \%$ on the largest instances, and four more gaps occured. In contrast, for bkmin $=1000$ the average iteration numbers grew by only $5-13 \%$ on the largest instances, and three gaps disappeared.

## A.4. Impact of various heuristics

Tables $46-51$ validate the discussion of $\S 5.7$ of the paper.
We first, consider the case where the heuristics H 1 through H 4 are replaced by the heuristic named H5, which consists in calling, upon bundle termination, Procedure 1 with Steps 2, 3 and 5 omitted, and Step 4 using FFD; in other words, the relaxed primal solution is rounded down and the residual problem is solved by FFD. The results for H 5 (with $\epsilon_{r}=10^{-5}$ ) given in Tables 46-48 show that H5 performs quite poorly relative to Tabs. 1-3 (and that H1 reduces the iteration numbers, and usually the computing times as well). On the other hand, we note that H5 solved $91.5 \%$ and $68.8 \%$ of problems in Tabs. $46-47$, whereas the FFD-based heuristic of Degraeve and Peeters (2003) solved $91.6 \%$ and $69.9 \%$; further, H5 solved $92.8 \%$ of problems in Tab. 48, whereas the corresponding heuristic RFFD of Wäscher and Gau (1996) solved $92.5 \%$. Thus our bundle results with H5 are very similar to those obtained with other CG solvers.

Our next improvement on H 5 , named H 6 , consists in calling Procedure 1 with only Step 2 omitted, and Step 4 using FFD. The results for H 6 given in Tables $49-51$ show that H6 performs much better than H5, solving $96.4 \%, 91.9 \%$ and $97.2 \%$ of problems; thus the rounding procedure of Belov and Scheithauer (2002) may yield significant improvements also for FFD. Finally, we note that H 2 and H 4 improve on H 6 by using SHP or SVC together with Step 2 of Procedure 1. Specifically, H 1 and H 2 solved $99.8 \%, 99.4 \%$ and $99.7 \%$ of problems, and together with H4 they solved $99.94 \%, 99.88 \%$ and $99.92 \%$ of problems.

## A.5. Comparisons with other procedures from the literature

## A.5.1. Comparison with Kiwiel and Lemaréchal (2007)

For convenience, Tabs. 52-54 replicate (Kiwiel and Lemaréchal, 2007, Tabs. 1-3). They may be compared with Tabs. 1-3, since they were obtained on the same machine.

## A.5.2. Comparison with Degraeve and Peeters (2003)

In Table 55 we compare the average running times of our fundle relaxation code BR with the two best procedures HR and LR of Degraeve and Peeters (2003) on the instances used for Tabs. 9, 10, 12 and 13. The times for HR and LR obtained on a Pentium Pro 200 MHz were extracted from (Degraeve and Peeters, 2003, Tabs. 1-4b). Two points should be noted. First, both HR and LR employed an industrial LP solver (much more sophisticated than

Table 55: Comparison of running times with Degraeve and Peeters (2003), int $=$ all

|  | Tab. 9 |  |  |  | Tab. 10 |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Tabs. 12-13 |  |  |  |  |  |  |  |
| $m$ | HR | LR | BR | LR | BR | LR | BR |
| 30 | 0.17 | 0.10 | 0.02 | 0.10 | 0.02 | 0.29 | 0.02 |
| 40 | 0.44 | 0.21 | 0.05 | 0.21 | 0.04 | 0.71 | 0.03 |
| 50 | 0.74 | 0.38 | 0.08 | 0.37 | 0.08 | 1.45 | 0.06 |
| 75 | 5.03 | 0.81 | 0.22 | 2.18 | 0.24 | 9.57 | 0.37 |
| 100 | 10.14 | 2.99 | 0.42 | 2.63 | 0.40 | 21.08 | 1.42 |

our dense QP solver), and LR additionally used subgradient optimization. Second, due to lacking knowledge, let's assume that the machine of Degraeve and Peeters (2003) was ten times slower than ours. Then Table 55 suggests that on the small-item-size instances BR was comparable in speed with HR (about twice slower than LR), while on the medium-item-size instances BR could perform better than LR. Similarly, in view of Tab. 3 and (Degraeve and Peeters, 2003, Tab. 10), on the instances of Wäscher and Gau (1996) BR was as fast as HR (twice slower than LR), whereas Tab. 4 and (Degraeve and Peeters, 2003, Tab. 5a) indicate that on the instances of Vanderbeck (1999) BR was comparable with HR, and sometimes faster than LR. On the industrial instances of Degraeve and Schrage (1999) (cf. Tab. 16 and (Degraeve and Peeters, 2003, Tab. 9)), BR behaved like HR (sometimes better than LR).

## A.5.3. Comparison with Briant et al. (2007)

We now compare our running times with those in (Briant et al., 2007, §2.2), where the task was just to produce sufficiently accurate primal and dual solutions $\hat{z}^{k}$ and $\hat{u}^{k}$ that satisfy the stopping criteria

$$
\begin{gather*}
e \hat{z}^{k}-\underline{\theta}_{k} \leq \tilde{\epsilon} \quad \text { and }  \tag{27a}\\
\left|\pi^{k}\right| / \sqrt{m} \leq \tilde{\epsilon} \tag{27b}
\end{gather*}
$$

for a given tolerance $\tilde{\epsilon}=10^{-6}$; thus the duality gap is at most $\tilde{\epsilon}$ and (since $\sum_{j} p^{j} \tilde{z}_{j}^{k}-d \geq \pi^{k}$ ) $\hat{z}^{k}$ satisfies the demand constraints within $\tilde{\epsilon}$ on the average.

However, the first criterion (27a) demands too much in the inexact case: To guarantee that it is eventually met we would need to assume that $\theta_{\hat{u}}^{\infty}-\underline{\theta}_{\infty}<\tilde{\epsilon}$; see below (25). Hence, to achieve a similar implementation context, our code was run with the second test (27b) added to our usual stopping criterion, and without early terminations due to primal heuristics. Table 56 gives our results for the instances of (Briant et al., 2007, §2.2); here "ind_ 9 " comprises the first 9 instances from Tab. 15, " 50 b 100 c 4 " is the final class of Tab. 4 and the remaining classes occur in Tab. 6. The columns " $e_{\mathrm{av}}$ " and " $e_{\mathrm{mx}}$ " give average and maxinum values of relative dual errors $\left|\theta_{*}-\underline{\theta}_{k}\right| /\left|\theta_{*}\right|$ (with $\theta_{*}$ estimated to at least 14 digits in other runs). The columns " $a_{\mathrm{av}}$ " and " $a_{\mathrm{mx}}$ " give average and maximum values of absolute errors $a_{k}$, with $a_{k}$ being the minimum $\tilde{\epsilon}$ satisfying (27); in other words, our code might have terminated earlier if we used (27) as the stopping criterion with $\tilde{\epsilon} \geq a_{m x}$.

Table 56 was obtained for $\epsilon_{r}=0$, i.e., exact KP solutions. The results for $\epsilon_{r}=10^{-5}$ are given in Tab. 57, and for $\epsilon_{r}=10^{-4}$ and $10^{-3}$ in Tabs. 58-59. The accuracy obtained was

quite poor for $\epsilon_{r}=10^{-3}$, a bit too weak for $\epsilon_{r}=10^{-4}$, but very good for $\epsilon_{r}=10^{-5}$ (the results for smaller $\epsilon_{r}$ were similar).

In view of the excellent accuracy in Tab. 57, in Tab. 60 we compare our bundle relaxation code BR using $\epsilon_{r}=10^{-5}$ with the three codes Kbasic, Krich and bundle of (Briant et al., 2007, Tabs. 1, 2 and 5), which implement two CG variants and an exact bundle variant respectively. We show the average ruming times " $t$ av" and the speedup of BR with respect to the fastest code of Briant et al. (2007), where the machine used was about twice slower than ours.

Note that on this fairly small set of 109 instances, there is little difference between exact bundle (Tab. 56) and standard inexact bundle (Tab. 57). Yet even this small set can illustrate the advantages of KP bound relaxation, another ingredient of our approach. Namely, Tabs. $56-59$ were obtained for the relaxed bounds of (9). For the tighter bounds of (8), Tabs. 61-64 exhibit significant slow downs on the first two classes ind_9 and 50b100c4.
